Abstract: Recent International Real Business Cycle (IRBC) models that assume complete international asset markets generate cross-country consumption correlations that are too high, when compared to the data. This paper shows that an IRBC model in which asset markets are incomplete (in the sense that only debt contracts can be traded in asset markets) can generate cross-country consumption correlations that are markedly lower. This improvement is achieved without significantly worsening predictions for other key business cycle statistics.

Key words: Incomplete asset markets; Risk Sharing; Business Cycles
Consumption. JEL classification: E32, F41, G15

The author is visiting the Economics Department at University College London in 1995/96 under the auspices of the Human Capital and Mobility programme (European Commission). He wishes to thank UCL for its hospitality.

This paper is based on a chapter of the author’s Ph.D. dissertation at the University of Chicago. Thanks are due to Michael Woodford for his guidance and to Patrick Kehoe for detailed suggestions. Thanks are also extended to a referee for detailed comments as well as to Lea-Anne Solomonian for editorial assistance. Financial support from the Bradley Foundation, the International Economic Workshop at the University of Chicago (supported by a grant from the Sloan Foundation) as well as from Fonds Marcel Faribault and Fonds CAFIR at Université de Montréal is gratefully acknowledged.
1. Introduction

In recent years, much effort has been devoted to extending the closed economy Real Business Cycle (RBC) model to an international setting (see McCallum, 1989, and Danthine and Donaldson, 1993, for surveys of the RBC literature). Authors such as Backus, Kehoe and Kydland (1992), Crucini (1989) and Baxter and Crucini (1993) have developed two-country RBC models. In these models, each country is inhabited by a representative agent. Countries interact by trading in goods markets and in financial markets. A central assumption in this recent work is that there exist complete international asset markets.

A striking shortcoming of available models of this type is that they tend to generate cross-country consumption correlations that are too high when compared to actual data. For example, different versions of the seminal two-country RBC model presented by Backus et al. (1992) produce cross-country consumption correlations in the range 0.69 to 0.95. In contrast, Backus et al. report that the correlation of (detrended) consumption in the United States and in an aggregate of European countries equals 0.46.

This study investigates whether an IRBC model with incomplete asset markets can change this prediction. The paper is motivated by the conjecture that the high cross-country consumption correlations generated by existing two-country RBC models reflect the assumption that asset markets are complete. After all, complete asset markets allow consumers to engage in extensive international risk pooling.

In this paper, a two-country RBC model is presented in which international asset markets are incomplete in the sense that only debt instruments (risk free bonds) can be used in international financial transactions. This structure of (incomplete) asset markets underlies permanent income models of consumption behavior and has also been used in much recent theoretical and applied work on small open economies (see, e.g., Cardia, 1991; Mendoza, 1991).

The elimination of trade in state contingent assets limits

---

1 Models of this type have also been studied by Dellas (1986), Cantor and Mark (1988), Finn (1990), Stockman and Tesar (1990), Backus and Smith (1992), Costello and Prashnik (1992), Devereux et al. (1992), Ravn (1992), Reynolds (1992), Bolleau (1993), Canova (1993), Yi (1993) and Bec (1994).
international risk sharing. A country affected by an idiosyncratic (country-specific) income shock can mitigate the effect of this shock on its consumption by trading in bonds. One may expect, however, that countries are less able to offset the effects of idiosyncratic income shocks when markets are incomplete than when markets are complete. Hence, one expects that consumption is less closely correlated across countries when markets are incomplete than in an Arrow-Debreu world.

The paper confirms this intuition. It shows that an IRBC model with incomplete asset markets can generate cross-country consumption correlations that are markedly lower and, hence, closer to the data, than those that obtain when complete asset markets are assumed. The assumption of incomplete asset markets also leads to improved predictions for other international comovements (for example, the incomplete markets model captures better the countercyclical behavior of net exports). These improvements are not achieved at the cost of significantly poorer predictions for other key business cycle statistics.

Section 2 of the paper presents the two-country model with incomplete markets. Section 3 briefly discusses an IRBC model with complete asset markets. Stylized facts about international business cycles are discussed in Section 4. Simulation results are presented in Section 5. Section 6 concludes.

2.1 Preferences and Technologies

The model considered in this paper follows rather closely the structure of earlier two-country RBC models (see, in particular, the models of Backus et al., 1992, and of Baxter and Crucini, 1993), except that here incomplete asset markets are assumed.

A world with two countries, indexed by i=1,2, is considered. Each country is inhabited by a representative consumer. There is a single good produced and consumed by both countries and also used as an investment good. There are no transportation costs or tariffs. Hence, there are no constraints on international flows of goods. Labor, however, is immobile internationally. The preferences of Country i's representative consumer are given by

$$V_t^i = E_t \sum_{\tau=0}^{\infty} \beta^\tau \ u(c_t^i, l_t^i),$$  \hspace{1cm} (1)
where $C_t$ is $i$’s consumption at date $t$ and $L_t$ is the number of hours worked. $0<\beta<1$ is the country’s subjective discount factor. $E_t$ denotes expectations conditional on period $t$ information. The period utility function $u$ is of the form

$$u(C,L) = \left(\frac{1}{1-\sigma}\right) \cdot \left( \frac{C \cdot (1-L)^{\mu}}{(1-\sigma)} \right)^{1-\sigma} - 1.$$  \hspace{1cm} (2)

$\mu>0$ and $\sigma>\mu/(1+\mu)$ are assumed in order to ensure that utility is increasing in $C$, decreasing in $L$ and strictly concave. In equation (2), the number of hours available to the representative agent at a given date has been normalized to one, so that $1-L$ represents the leisure of the agent.

Country $i$’s output in period $t$ is given by:

$$y_t^i = \theta_t^i \cdot (K_t^i)^{1-\eta} \cdot (L_t^i)^{\eta}.$$  \hspace{1cm} (3)

Here, $\theta_t^i$ is an exogenous productivity index and $K_t^i$ is Country $i$’s capital stock. The law of motion of capital is:

$$K_{t+1}^i = \phi(K_{t+1}^i, K_t^i) = (1-d) \cdot K_t^i + I_t^i,$$  \hspace{1cm} (4)

where $I_t^i$ denotes how much output is required to change the capital stock from $K_t^i$ to $K_{t+1}^i$. $0<\delta<1$ is the depreciation rate of the capital stock and $\phi(.,.)$ is a convex adjustment cost function that is homogeneous of degree one in $K_{t+1}^i$ and $K_t^i$:

$$\phi(K_{t+1}^i, K_t^i) = 0.5 \cdot \phi \cdot \left( \frac{K_{t+1}^i - K_t^i}{K_t^i} \right)^2.$$  \hspace{1cm} (5)

2.2 The Structure of Asset Markets

The key difference between the present model and standard IRBC models is that only risk free one-period real debt contracts can be used in financial markets. Besides the fact that labor is immobile internationally, this is the only restriction on international transactions that will be assumed. The assumption that agents’ financial transactions are restricted to risk free bonds is a key assumption in permanent income models of consumption behavior (see, e.g., Sargent, 1987, Ch.12). This asset markets structure has also been assumed in much recent theoretical and applied work on small open economies.2

Interesting alternatives to the incomplete markets structure discussed in the present paper might be structures where debt contracts and a limited

---

set of state contingent assets, such as stocks (residual claims), can be traded internationally (see, e.g., Cole, 1988). Because of its simplicity, the model with pure borrowing and lending will provide a useful benchmark for research on these more complex asset market structures. In recent monetary open economy models (see, e.g., Grilli and Roubini, 1991; McCurdy and Ricketts, 1991; Schlagenhauf and Wrase, 1992), agents face cash-in-advance constraints for their consumption purchases. Constraints of this type too could help to reduce the cross-country consumption correlation compared to the correlations that obtain in an Arrow-Debreu world.

With asset transactions restricted to one-period bonds, Country i's budget constraint in period t is:

$$C_t^i + I_t^i + A_t^i = Y_t^i + (1+r_{t-1}) \cdot A_{t-1}^i,$$  (6)

where $A_{t-1}^i$ is the country's (net) stock of one-period bonds that become due in period t and $r_{t-1}$ is the real interest rate on these bonds ($A_{t-1}^i > 0$ if the country is a lender).

Country i's decision problem is to maximize the lifetime utility defined in (1) subject to the constraint that the budget constraint (6) holds in all periods and for all states of the world. First-order conditions for this decision problem are provided in the Appendix.

Given exogenous productivity processes $\{\theta_t^i\}$ for $i=1,2$, an equilibrium with incomplete asset markets is a set of stochastic processes for the endogenous variables $\{C_t^1, I_t^1, K_t^1, A_t^1, r_t\}$ for $i=1,2$ that satisfies the first-order conditions listed in the Appendix and the budget constraints of the two countries, as well as the condition that the bond market clears:

$$A_t^1 + A_t^2 = 0 \text{ for all } t.$$  (7)

By Walras' law, equilibrium in the loan market implies that the goods market clears as well.

2.3 The Solution Method

An approximate solution of the model is obtained by taking a linear approximation of the equilibrium conditions around a deterministic steady state (i.e., around an equilibrium in which all endogenous and exogenous variables are constant). This approximation yields a system of...
expectational difference equations that is solved using the method outlined in Blanchard and Kahn (1980).

3. Complete Asset Markets

The source of uncertainty in the model is given by exogenous shocks to total factor productivity. With complete asset markets (Arrow-Debreu markets), agents can trade claims with pay-offs that are contingent on those productivity shocks. This structure of asset markets guarantees that competitive equilibria are Pareto optimal. Pareto optima can be found by imagining that in some "initial" period \( t=0 \), the following planning problem is solved:

Maximize \( \lambda \cdot V^1_0 + (1-\lambda) \cdot V^2_0 \),

subject to the constraint that the following world resource constraint holds in all periods \( t \geq 0 \) and for all states of the world:

\[
C^1_t + C^2_t + I^1_t + I^2_t = V^1_t + V^2_t.
\]

In (8), \( V^1_0 \) is Country i's expected lifetime utility at date \( t=0 \) (see equation [1]). The weights \( \lambda \) and \( 1-\lambda \) (with \( 0 < \lambda < 1 \)) reflect the wealth of the two countries (see, e.g., Rebelo, 1988a, 1988b).

One of the first-order conditions of this planning problem is that marginal utilities in the two countries (weighted by \( \lambda \) and \( 1-\lambda \), respectively) are equated (for discussions of this condition see, e.g., Scheinkman, 1984; Leme, 1984; Kollmann, 1991, 1995). When the utility function (2) is assumed, this risk sharing condition can be expressed as:

\[
\lambda \cdot (C^1_t)^{-\sigma} \cdot (1-L^1_t)^{-1} = (1-\lambda) \cdot (C^2_t)^{-\sigma} \cdot (1-L^2_t)^{-1}.
\]

In the special case where labor supplies are fixed, this condition implies that \( v^1_t = \Lambda \cdot v^2_t \), where \( \Lambda > 0 \) is a constant. In other words, then consumption is perfectly positively correlated across countries. The same prediction obtains also when \( \sigma = 1 \) (even when hours are variable) as then the period utility function is additively separable in consumption and hours (which implies that variations in hours do not affect the marginal utility of consumption). When hours vary and/or the utility function is

the simulations reported below, the model is linearized around a symmetric deterministic steady state in which all variables have the same values in both countries.

\(^4\)When \( \sigma = 1 \), the utility function (2) becomes: \( u(C,L) = \ln(C) + \mu \cdot \ln(1-L) \).
non-separable, then the cross-country consumption correlation is smaller than unity, even when asset markets are complete.

The risk sharing condition (10) implies also that intertemporal marginal rates of substitution in consumption are equated across countries, and that for all possible states of the world (see, e.g., Obstfeld, 1993). In contrast, when asset markets are incomplete, then intertemporal marginal rates of substitution are merely equated in expected value.\(^5\) As a result, one suspects that consumption is less closely correlated across countries when asset markets are incomplete.

In the simulations of the model with complete asset markets reported below, equal welfare weights are attached to the two countries. The linear approximation method described in Section 2.3 is used to solve numerically the complete markets model.

4. Stylized Facts on International Business Cycles

The column labeled "Data" in Table 1 presents key statistics that describe the properties of quarterly macroeconomic time series for the G-7 countries. The sample period is 1970:1-1991:3. All statistics are based on series that were detrended using the Hodrick and Prescott (1980) filter (henceforth, HP filter). Except for series on the ratio of net exports to output, logarithms of all series were taken before applying the HP filter. To save space, only average statistics for the G-7 countries are reported (Backus et al., 1992, and Kollmann, 1991, present more detailed descriptive statistics on international business cycles). For example, the cross-country correlations reported in the "Data" column are averages of cross-country correlations computed for all pairs of G-7 countries (data sources and the definitions of the variables used to construct the statistics in the "Data" column are provided in the Appendix).

For the G-7 countries, the (average) cross-country correlations of output, of consumption and of investment are 0.46, 0.34 and 0.45, respectively.\(^5\)

\(^5\)As the Euler condition (1) in the Appendix holds for \(i=1,2\), one sees that \(\beta \cdot E_t u_1(c_{t+1}^{-1},L_{t+1})/u_1(c_{t+1}^{-1}) = \beta \cdot E_t u_1(c_{t+1}^2,L_{t+1})/u_1(c_{t+1}^2,L_{t+1})\), where \(u_1\) denotes the marginal utility of consumption. In contrast, \(\beta \cdot u_1(c_{t+1}^{-1},L_{t+1})/u_1(c_{t+1}^{-1}) = \beta \cdot u_1(c_{t+1}^2,L_{t+1})/u_1(c_{t+1}^2,L_{t+1})\) holds when asset markets are complete.
Domestic investment is closely correlated with domestic saving. It can also be seen that investment is more volatile than output, while hours worked and consumption are less volatile than output. These variables are all highly serially correlated. Consumption, investment and hours are strongly procyclical (positively correlated with output), while net exports are countercyclical. These stylized facts on cyclical fluctuations do not depend on the HP filter; other detrending methods (e.g., linear detrending) lead to similar empirical regularities.

5. Simulations

5.1 The Parameters of the Model

The depreciation rate $d$ is set to 0.021, which corresponds to the quarterly depreciation rate estimated by Christiano and Eichenbaum (1992) using post-war U.S. data. In the model, the share of output going to labor is given by the parameter $\eta$. For the U.S., the average value of the ratio of the compensation of employees to GDP (net of indirect taxes) is approximately 0.64 (similar values obtain for the other countries in the sample) and, hence, $\eta=0.64$ is assumed. As is common in the RBC literature (e.g., King et al., 1988), the steady state interest rate is set equal to the observed average real return on equity. As documented by Mehra and Prescott (1985), the long run average annual real return on equity in the U.S. is 7% and, hence, $r=0.0175$ is used (as the model is calibrated to quarterly data). These (or very similar) values of $\delta$, $\eta$ and of the steady state interest rate are generally used in RBC models. The adjustment cost parameter $\phi$ is set to $\phi=3$ in order to match the observation that the standard deviation of investment is approximately 3.3 times as large as that of output (for lower values of $\phi$, investment is excessively volatile).

As is common in the RBC literature (see, e.g., Prescott, 1986; Hansen and Wright, 1992), the preference parameter $\mu$ is selected in such a way that, in steady state, agents devote one-third of their time to work, which

6. The empirical consumption measure used in the "Data" column is private consumption of non-durables and services.

7. This requires that $\beta=0.9828$ is assumed, as $\beta\cdot(1+r)=1$ holds in steady state.

8. It appears that, for this value of $\phi$, the average capital adjustment cost amounts to less than 0.01% of output.
requires $\mu=1.59$ (empirical studies on the allocation of time suggest that adults in industrialized countries devote roughly one-third of their non-sleeping time to market work; see Juster and Stafford, 1991).

The baseline case assumes that the coefficient of relative risk aversion is $\sigma=2$. This value lies in the range of risk aversion coefficients usually assumed in RBC studies (Friend and Blume, 1975, present empirical evidence suggesting that the relative risk aversion coefficient is in the range of 2; other estimates of that coefficient lie between 0 and 5 — see, e.g., Hansen and Singleton, 1983; Dunn and Singleton, 1986).

Productivity follows a vector autoregressive process:

$$z_t = R \cdot z_{t-1} + \epsilon_t,$$

where $z_t=(\ln(\tilde{y}^1_t), \ln(\tilde{y}^2_t))'$ is the vector of productivities in the two countries, expressed in logs. The vector $\epsilon_t=(\epsilon^1_t, \epsilon^2_t)'$ is i.i.d. with mean zero and covariance matrix $\Omega$. The simulations assume

$$R = \begin{bmatrix} 0.95 & 0 \\ 0 & 0.95 \end{bmatrix} \quad \text{and} \quad \Omega = 0.007^2 \begin{bmatrix} 1 & 0.2 \\ 0.2 & 1 \end{bmatrix}.$$  

As is common in the RBC literature, productivity is thus assumed to be highly serially correlated. This specification implies that the cross-country productivity correlation is 0.20. \(^9\)

5.2. Simulation Results

Tables 1 and 2 report the simulation results. The model statistics reported in the tables are averages of moments calculated for 1000 simulations with a sample length of 37 periods each (this number of periods corresponds to the length of the empirical data set). All simulated series were passed

\(^9\) Prescott (1986) presents evidence that the autocorrelation of productivity is in the range of 0.95, and RBC studies usually use this value or one close to it (e.g., Hansen, 1985; Gomme, 1993; Ambler and Paquet, 1994). Hence, an autocorrelation of 0.95 is assumed in this study. The standard deviation of the productivity innovation in Country $i$ ($\epsilon^i_t$) is set to 0.007, as this is approximately the value for the standard deviation of productivity innovations suggested by Prescott (1986). To check whether the $R$ matrix assumed in (12) is consistent with the data, (11) was fitted for all pairs of G-7 countries (using the productivity series described in the Appendix, a linear time trend was also included in the regressions). The estimated $R$ matrices are generally compatible (at conventional significance levels) with (12).

\(^{10}\) For the G-7 countries, the average cross-country correlation of HP filtered total factor productivity is 0.25 (for linearly detrended productivity, the average correlation is 0.22).
through the HP filter before the model statistics were computed.

To formally evaluate how close the predicted statistics are to the data, the methodology developed by Gregory and Smith (1991) was used. The proportion of the 1000 simulations was determined in which the cross-country consumption correlation generated by the model was smaller than the empirical consumption correlation of 0.34. Let \( \pi \) denote this fraction of trials. \( \pi \) and \( 1-\pi \) can be interpreted as probability values for one-sided tests of the hypothesis that the cross-country consumption correlation generated by the model is compatible with the data (values of \( \pi \) close to zero or to unity indicate a rejection of this hypothesis).\footnote{The Gregory and Smith (1991) methodology was also used to compute 95\% confidence intervals for each of the statistics considered in Tables 1 and 2 (these intervals run from the 0.025 to the 0.975 quantiles of the frequency distribution of the simulated statistics that obtain when the model is simulated 1000 times). In the tables, a \( \dagger \) next to a theoretical statistic indicates that the 95\% confidence interval for that statistic includes the empirical moments reported in the "Data" column.}

Table 1 considers the \textit{baseline} specification. The cross-country consumption correlation is 0.72 when markets are complete and 0.38 when markets are incomplete. The associated Gregory-Smith probability values are \( \pi=0.00 \) (complete markets) and \( \pi=0.40 \) (incomplete markets). When asset markets are incomplete, the cross-country consumption correlation is thus significantly closer to the data.

Table 1 shows that the assumption of incomplete asset markets also leads to improved predictions for other international comovements. For example, the correlation between net exports and output is markedly lower (and closer to the data) when markets are incomplete. Like previous IRBC models that assume a single good (e.g., Backus et al., 1992), the present model underpredicts the cross-country correlations of output, investment and hours worked (Stockman and Tesar, 1990, show that an IRBC model with multiple goods can generate cross-country output correlations that are more consistent with the data). The assumption of incomplete markets does not overcome this shortcoming. However, cross-country correlations of output, investment and hours are larger (and hence closer to the data) when asset
Assuming incomplete markets has a fairly weak effect on the remaining statistics considered in Table 1. Some predictions worsen somewhat, while others improve slightly. For example, the relative standard deviation of hours, which is already too low when markets are complete, falls somewhat when incomplete markets are assumed. On the other hand, the relative standard deviation of consumption, which likewise is too small when asset markets are complete, increases when risk sharing is restricted. Note also that, as the two-country RBC model of Baxter and Crucini (1993), the present model predicts that, within the same country, saving is closely correlated with investment (this prediction obtains irrespective of the structure of asset markets).

[INSERT TABLE 2 ABOUT HERE]

Alternative specifications
Table 2 changes the model specification compared to the baseline case. The columns labeled "Fixed Hours" in Table 2 assume that labor supplies are fixed. It seems interesting to consider the "Fixed Hours" case because, as discussed above, the complete markets model predicts that consumption is perfectly correlated across countries when labor supplies are fixed. Table

12 To get an intuition for these findings, consider the effects of an increase in productivity that occurs, say, in Country 1. Simulations show that hours worked and investment increase in Country 1. Also, the interest rate rises, which lowers Country 2 investment (hence, the negative cross-country investment correlations reported in Table 1). When markets are complete, the Country 1 productivity shock induces a positive wealth effect in Country 2 which implies that Country 2 hours fall (i.e., the sign of the response of hours worked differs in the two countries). When markets are incomplete, this other-country wealth effect is not present. In addition, Country 1 wealth rises more strongly when markets are incomplete, which dampens the rise in Country 1 hours and strengthens the rise in Country 1 consumption. This explains why net exports are more countercyclical and why the cross-country hours correlation is higher when markets are incomplete (the higher cross-country hours correlation helps explain why the cross-country correlations of output and investment are higher when markets are incomplete).

13 But most of the other statistics are basically unaffected when incomplete markets are assumed.

14 To save space, Table 2 only reports cross-country correlations of consumption and output. The remaining predictions are, on the whole, rather similar to those which obtain in the baseline case (detailed simulation results are available on request).
2 shows that, in contrast, the cross-country consumption correlation is 0.51 when markets are incomplete (the associated Gregory-Smith probability value is \( \pi=0.11 \)). It thus appears again that assuming incomplete asset markets leads to a marked reduction of the cross-country consumption correlation.

It also seems interesting to vary the risk aversion coefficient. In the columns labeled "High Risk Aversion" the risk aversion coefficient is raised to \( \sigma=5 \). For both asset market structures, this lowers the cross-country consumption correlation compared to the baseline case.\(^{15}\) However, the cross-country consumption correlation remains markedly lower when markets are incomplete (0.28) than when markets are complete (0.55).\(^{16}\)

6. Concluding Remarks

This paper has presented a two-country RBC model in which asset markets are incomplete—in the sense that only debt contracts can be traded in international financial markets. The model can generate cross-country consumption correlations that are markedly lower and, hence, closer to the data, than the cross-country consumption correlations that obtain when asset markets are complete.

\(^{15}\)When \( \pi \) is raised, variations in hours worked have a stronger impact on the marginal utility of consumption (Note: the elasticity of the marginal utility of consumption with respect to hours is \(-\mu\cdot(1-\sigma)\cdot L/(1-L)\)). As hours fluctuations have a large country-specific component, this helps explain why consumption comoves less closely in the two countries when \( \sigma \) is raised.

\(^{16}\)The associated Gregory-Smith (1991) probability values are \( \pi=0.60 \) (incomplete markets) and \( \pi=0.08 \) (complete markets).
APPENDIX

A. THE MODEL WITH INCOMPLETE ASSET MARKETS: FIRST-ORDER CONDITIONS

Ruling out Ponzi schemes, the solution of the decision problem of Country $i$ satisfies the following Euler conditions:

$$u_{i,t}^1 = (1+r_t^i)^*E_t^i u_{i,t+1}^1$$  (1)

and

$$u_{i,t}^1 = \beta \cdot E_t^i \cdot MPK_{t+1}^i \cdot u_{i,t+1}^1$$  (II)

Here $\text{MPK}_{t+1}^i \equiv \left( f_{1,i,t+1}^i + \phi_{1,i,t+1}^i \right) / (1+\phi_{1,i,t+1}^i)$ is Country $i$'s intertemporal marginal rate of transformation between output in periods $t$ and $t+1$, while $u_{s,t}^i$, $f_{s,t}^i$ and $\phi_{s,t}^i$ denote the derivatives of $u(C_{s,t}^i)$, $f(K_{s,t}^i,L_{s,t}^i)$ and $\phi(K_{s,t}^i,L_{s,t}^i)$ with respect to the $s^{th}$ argument of these functions. In addition, Country $i$ equates its marginal rate of substitution between labor and consumption to the marginal product of labor:

$$u_{2,t}^i + \theta_{1,i,t}^i \cdot (K_{1,t}^i)^{1-\eta} \cdot (L_{1,t}^i)^{\eta} \cdot u_{1,t}^i = 0.$$  (III)

B. DATA APPENDIX

The "Data" column of Tables 1 and 2 reports statistics that are averages of empirical statistics computed for the G-7 countries. For example, the within-country statistics reported in the "Data" column are arithmetic averages of statistics computed for each of the G-7 countries (e.g., the empirical statistic for consumption reported under the sub-heading 'Standard Deviations Divided by Standard Deviation of Output' was obtained by computing the ratio of the standard deviation of consumption to the standard deviation of output for each G-7 country and taking the average value of this ratio for the G-7 countries). Empirical cross-country correlations reported in the "Data" column are averages of cross-country correlations computed for all pairs of G-7 countries.

Empirical series used for statistics reported in "Data" column of Tables 1 and 2: output--GDP; consumption--private sector consumption of non-durables plus services; investment--gross fixed capital formation; net exports--exports of goods and services minus imports of goods and services; saving--GDP minus total private consumption minus government consumption (in model, saving defined as $Y-C$). All empirical variables are quarterly (1970:1-1991:3); they are in per capita terms and in constant prices.
Data Sources and Definition of Variables

GDP, Gross Fixed Capital Formation, Government Consumption, Total Private Consumption, Exports of Goods and Services, Imports of Goods and Services: These series are taken from International Financial Statistics (IFS). They are provided in current prices by IFS. The series were deflated using the IFS consumer price index. The investment series include public investment.

Private Consumption of Non-Durables and Services: expenditures on non-durables and services (in constant prices) from OECD Quarterly National Accounts.

Hours of Work: The following series were used. U.S.--total employee hours (from establishment survey) were taken from Citibase (series LPMHU). Japan, France--an index of total hours worked was constructed by multiplying the series "paid employment in non-agricultural establishments" and "weekly hours of work in the non-agricultural sector" from the Bulletin of Labour Statistics published by the International Labour Office (ILO) (for Japan, the hours series for employees was used). United Kingdom--total employment multiplied by average weekly hours worked (from Employment Gazette, Supplement with Historical Statistics, 1992). This source provides hours data at annual frequency only. A quarterly U.K. hours series was constructed by linear interpolation. Italy--total employment (not hours) in non-agricultural sector (from ILO). Canada--1975-1991: total hours worked (all jobs); before 1975: total employment (series from Historical Labour Force Statistics 1991, Statistics Canada).

Capital Stock: U.S.--private plus government owned fixed capital (at constant cost); source for 1971-1990: Musgrave (1992), Table 4. The U.S. capital stock for 1991 was estimated by assuming that the growth rate of capital between 1990 and 1991 equaled the average growth rate during 1971-1990. Japan, Germany, France, U.K., Canada--for 1971-1989, data on total net stocks of capital in constant prices were taken from Flows and Stocks of Fixed Capital (OECD). Italy--1971-1985 capital stock data in constant prices were taken from the Intersectoral Database (OECD). The Italian capital stock for 1986-1989 was estimated by assuming that during each of these three years, the share of Italian physical capital in the total capital stock of the G-7 countries (other than the U.S.) equaled the share observed in 1985. Capital stocks for 1990-1991 were estimated by assuming that for each country the growth rate of the capital stock between 1989 and 1991 equaled the average growth rate during of capital in that
country during the period 1971-1989. All Capital stock data from these sources are annual. Quarterly capital stock series were constructed by linear interpolation.

**Population:** International Financial Statistics. Quarterly series were constructed from annual figures using linear interpolation.

**Total factor productivity:** TFP series were obtained according to the method described in Solow (1957). For this purpose, the GDP, capital stock and hours series described above were used, as well as time series for the share of labor earnings in output. The latter were constructed as follows: for each country, data from the OECD National Accounts were used to construct an annual series (for 1970-1991) for the ratio (compensation of employees paid by resident producers)/(GDP minus indirect taxes plus subsidies). To obtain a quarterly labor share, it was assumed that the labor share is constant during all quarters of the same year.

Series that are not provided in seasonally adjusted form by the data sources were adjusted with the Census X-11 seasonal adjustment procedure (using the EZ-X11 program available from Doan Associates, Evanston, IL.).

</table>

Note: The "Data" column reports empirical statistics for the G-7 countries. See the Appendix for detailed information on the data. "Standard deviations relative to output" are standard deviations of consumption, investment etc., divided by standard deviation of output. "Net Exports/output" is ratio of net exports to output. The statistics in columns 1 and 2 are averages over 1000 simulations of 87 periods each. All statistics are based on HP filtered series. † indicates that a 95% confidence interval includes the empirical statistic reported in the "Data" column (the 95% confidence intervals run from the 0.025 to the 0.975 quantiles of the frequency distribution of the simulated statistics).

Note.—The columns labeled "Fixed Hours" assume that labor supply is completely inelastic. The "High Risk Aversion" experiment assumes $\sigma=5$. + indicates that a 95% confidence interval includes the empirical statistic reported in the "Data" column (the 95% confidence intervals run from the 0.025 to the 0.975 quantiles of the frequency distribution of the simulated statistics). See Table 1 for additional explanations.
